A B S T R A C T

This study investigated the effect of mechanical infection control for periodontitis and periodontal surgery on the prevalence of well-established risk factors for atherosclerosis, and plasma levels of cytokines, antibodies against heat shock proteins and markers of systemic inflammation. Sixty-eight patients between 39 and 73 years of age with severe periodontitis who had been referred to four specialist periodontology clinics in Sweden were investigated. A fasting venous blood sample was taken at baseline and additional samples were collected after 3 and 12 months. A total of 54 patients underwent periodontal treatment. The periodontal treatment was successful, as pathogenic gingival pockets decreased significantly. Plasma glucose, lipids and markers of systemic inflammation were not significantly altered after 3 months. One year after the initial treatment, HDL-C concentrations were significantly increased (Δ0.08 mmol/L) whereas LDL-C concentrations decreased (Δ0.23 mmol/L). Haptoglobin concentrations were also lower. Interleukin-1β and interferon-γ levels were also lower after 12 months (60 ng/L (−23%) and 11 ng/L (−97%) respectively). Treatment had no effect on plasma levels of IgA, IgG1, IgG2 antibodies against heat shock proteins.

In conclusion, this study indicates that standard treatment for periodontal disease induces systemic changes in several biochemical markers that reflect the risk for atherosclerosis.

1. Introduction

Periodontitis is a chronic tissue-destructive inflammatory state which is predominantly induced by Gram negative bacteria colonizing the gingival crevice. The disease degrades the attachment apparatus of the teeth, leading to tooth loosening and eventually, in its most severe form, to tooth loss. Periodontitis is a common disease; the U.S. National Health and Nutrition Examination Survey 1999–2000 (NHANES) reported a prevalence of 4.2% among adult Americans [1]. Conventional treatment of periodontitis comprises mechanical removal of supra- and subgingival bacteria which decreases inflammation and promotes clinical signs of healing and repair.

A meta-analysis of longitudinal and cross-sectional studies recently demonstrated that patients with periodontitis are at a significantly elevated relative risk of developing cardiovascular disease (CVD) [2]. One possible explanation for this could be the spread of bacteria and bacterial products into the circulation, and in this respect DNA from oral bacteria has been found in atherosclerotic plaques [3]. Periodontal pathogens and their products have been reported and purported to trigger the atherosclerotic process in animal and human studies [4–6]. In addition to the spread of bacteria, the release of host-derived inflammatory mediators such as C-reactive protein (CRP) and cytokines from the chronically inflamed periodontal tissues into the circulation might provide a link between periodontal disease and CVD, as it is known that chronic infection and inflammation predispose individuals to the development of CVD (for review see van Leuven et al. [7]).
We have previously reported that levels of CRP and lipoproteins are significantly different in those with periodontitis compared with a healthy control group [8]. It is not clear whether these differences trigger or are a consequence of the local inflammation in the periodontium. Thus, the aim of the present study was to investigate the effect of a clinically successful mechanical infection control protocol on well-established risk factors for CVD such as hyperglycemia and dyslipidemia. Furthermore, we investigated the effect of periodontal treatment on the levels of plasma cytokines, antibodies against heat shock proteins and markers of systemic inflammation.

2. Methods

2.1. Participants

Sixty-eight patients (all Caucasians; 36 women) with severe periodontitis (having a minimum of seven sites exhibiting at least 6 mm loss of clinical attachment) participated in the clinical examination and blood sampling. Twenty-nine (43%) of the participants were current smokers. The mean age was 53.8 ± 7.9 years. To be included in the study, patients had to have a chronic generalized severe periodontitis [13] and be between 35 and 70 years of age. They also had to be overtly healthy and free of CVD, not to be taking any medications for CVD and not to be suffering from any known systemic diseases. Their mean body mass index (BMI) was 25.9 (SD 3.3). Patients meeting the inclusion and exclusion criteria were consecutively selected.

All participants gave their informed consent. This study was approved by the Regional Ethics Committee of the Karolinska Institutet, and it was conducted in accordance with the Helsinki Declaration.

2.2. Clinical examination for periodontal disease

Patients underwent a comprehensive periodontal examination including radiographs. A total of four dentists, all with extensive experience in the field of periodontology, undertook the clinical examinations. The examiners were given detailed instructions beforehand. Teeth and gingivae were evaluated, and pocket depths were measured using a calibrated periodontal probe. Probing depth is the distance between the gingival margin and the bottom of the gingival pocket measured from six angles of each tooth. Gingival pockets of 4 mm or deeper were considered to be pathological. Gingival inflammation was noted as bleeding on probing and data are expressed as the proportion of bleeding sites among the total number of sites in the dentition. A first fasting blood sample was taken after the examination, but before treatment began.

2.3. Clinical treatment of periodontal disease

Patients underwent a thorough periodontal treatment, including extractions of hopeless teeth due to periodontitis, caries lesions or endodontic reasons. Oral hygiene instructions were given and scaling and root planing was performed. This is the standard care for reducing periodontal inflammation. The treatment continued until the patient achieved a good status of oral hygiene by him/herself and was free from clinically detectable calculus [13]. Patients were re-examined according to the baseline criteria after 3 months and a second blood sample was taken. For those who still had pockets deeper than 6 mm, a standardized periodontal muco-periosteal flap surgical procedure was performed [9]. The patients were re-examined and a final fasting blood sample was taken after 12 months (see Fig. 1).

3. Laboratory analyses

Blood was collected into Vacutainer™ tubes containing EDTA and hematological parameters were determined using a Coulter STKS analyzer (Coulter Electronics Inc., Hialeah, FL, USA). Plasma was obtained after centrifugation at 1500 × g for 10 min and stored at −70 °C. Total cholesterol, low density lipoproteins cholesterol (LDL-C) and high density lipoprotein cholesterol (HDL-C) concentrations were determined using standard clinical chemistry procedures with a Hitachi 917 analyzer (Roche AG Diagnostics, Mannheim, Germany). The lipid profile was calculated as the ratio between total cholesterol and HDL-C. CRP concentrations were determined using a high-sensitivity commercial assay kit (DADE Behring, Deerfield, IL, USA) and haptoglobin and fibrinogen concentrations were measured using a BNA nephelometer (Behringerwerke AG Diagnostica, Marburg, Germany).

Interleukin (IL)-1β, IL-4, IL-5, IL-6, IL-8, IL-10, interferon-γ (IFN-γ) and tumor necrosis factor-α (TNF-α) concentrations were determined by Multiplex bead analysis using a Luminex 100 (Luminex Corp., Austin, TX, USA) and commercial immunoassays (Lincoplex, high-sensitivity human cytokine panel, Linco Research Inc., St. Charles, MO, USA). IL-18 concentrations were determined using a commercial immunoassay kit according to the manufacturers’ recommended protocols (R&D Systems Europe Ltd., Abingdon, UK). Glucose concentrations were determined using a Beckman-Coulter LX analyzer (Beckman-Coulter Inc., Fullerton, CA, USA). All blood analyses were performed blindly.

Levels of plasma antibodies against human Hsp60 (kindly provided by Professor Willem van Eden and Dr. Ruurd van de Zee, Utrecht University, Utrecht, The Netherlands), mycobacterial Hsp65 (kindly provided by Professor Anthony Coates, St. George’s Hospital Medical School, London, UK), and human Hsp70 (kindly provided by Professor Gabrielle Mullhoff, Klinikum rechts der Isar (Technische Universität München), Munich and Helmholtz Zentrum München, German Research Center for Environmental Health, Neuherberg, Germany) were determined as described previously [8,10], except that the levels of specific antibody isotypes/sub-types (IgA, IgG1, IgG2) were determined. Data are presented as the absorbance values that were generated by 1/100 dilutions of the samples. All samples were analyzed at the same time and under identical conditions.

3.1. Statistical methods

The data were analyzed using a mixed model in Procedure Mixed in SAS® in order to establish whether there were any treatment effects over time (three time points) on lipid and inflammatory variables. Post hoc comparisons between visits were undertaken if the F-test was significant. The p-values were adjusted according to Tukey’s procedure. Since the distribution of some variables was
positively skewed, log transformation and square root transformation were performed before the analyses. Significant differences between smokers and non-smokers were calculated using the Mann–Whitney U-test or Student’s t-test. Correlative statistics were undertaken using the Spearman Rank Order test. Statistical calculations were made with Statistica 8.0, StatSoft® Inc., Tulsa, OK, USA, and SAS® System 9.1, SAS Institute Inc., Cary, NC, USA.

4. Results

Of the 68 patients that were initially identified to be included in the study, 54 completed the 1-year follow-up period. The other 14 failed to complete their treatment plan due to various reasons, such as lack of money, interest or the fact that they had moved and declined to participate. Gender distribution, smoking, mean age, BMI, CRP, glucose and cholesterol concentrations at baseline did not differ between all participants and those continuing the study. To our knowledge, none of the individuals in the smoking group stopped smoking during the study period.

The clinical outcome of the treatment program is shown in Table 1. The treatment successfully reduced the intensity of local infection and inflammation. Clinical markers of the disease, pathogenic gingival pockets (≥4 mm), bleeding on probing (BOP), and visual bacterial plaque were decreased significantly. There were no differences between smokers and non-smokers at baseline. However, significant differences in the number of pockets and BOP after 3 months and BOP after 12 months between smokers and non-smokers were apparent, thereby indicating that smokers were somewhat less responsive to treatment. Possible correlations between clinical status and plasma variables were tested at baseline. None of the investigated plasma variables were correlated with the clinical status.

Plasma glucose, lipids and the markers of systemic inflammation were not significantly different at the 3-month follow-up. One year after the initial treatment, glucose and HDL-C concentrations were significantly higher than baseline (Δ0.08 mmol/L), whereas LDL-C concentrations were lower (Δ0.23 mmol/L). The lipid profile and haptoglobin concentration were also lower than baseline at this time (Tables 2 and 3). IL-18 levels were decreased after 3 and 12 months, with the median decrease at 12 months being 0.25 mmol/L (−23%). The decreases in IL-18 and IFN-γ levels did not correlate with the observed clinical improvements in periodontal health. Treatment had no effect on the levels of any of the other cytokines measured, and there were no correlations between the dental parameters and the changes in lipid levels.

The concentrations of IgA, IgG1, IgG2 antibodies against human Hsp60, mycobacterial Hsp65 and human Hsp70 were not influenced by periodontal treatment (data not shown).

5. Discussion

This intervention study indicates that periodontal treatment influences blood lipid levels in a manner which is consistent with a decreased risk for CVD. HDL-C concentrations increased and LDL-C concentrations decreased significantly. The changes were modest; LDL-C concentrations decreased by 6%. HDL-C concentrations slowly increased during the 12-month study period, which corresponds well with the periodontal infection treatment. Both chronic and acute infections decreased circulating HDL-C concentrations by various mechanisms, including an increase in apolipoprotein A-1 catabolism and changes in HDL-C subclass distribution [11,12]. The observed decrease of LDL-C concentration may be due to alterations in lipase and lipid transfer protein activities, as well as expression levels of LDL-C receptors. As a caveat, it should be noted that this study did not follow a group of untreated patients with periodontitis over the same time. Natural fluctuations in the levels of measured analytes might occur. It cannot therefore be ruled out that the reduction in LDL-C levels and increase in HDL-C levels, and the observed changes in other plasma variables, might reflect normal fluctuations, rather than any direct impact of periodontal treatment. The inclusion of such a control group would require the withholding of an important clinical intervention, which would have ethical implications.

Although studies have shown there to be an association between periodontitis and CVD, a definitive causal relationship has not yet been demonstrated. If a standard periodontal treatment could positively influence established risk markers for CVD, then this could be interpreted as sign of causality. Previous intervention studies suggest that periodontal treatment decreases the levels of inflammatory markers such as CRP, fibrinogen and IL-6 [12,14]. However, these studies were fairly small and the follow-up periods were only between 3 and 6 months. In the present study, the follow-up is longer and the treatment also included extractions and periodontal surgery; some of the previous intervention studies have only investigated the consequences of non-surgical debridement [14,15]. The mean plasma concentrations of glucose increased by 0.25 mmol/L, however the reason for this is unclear. Earlier studies have shown that periodontal treatment can have some effect on glucose concentration in patients with diabetes, especially those with type 2 diabetes [16]. The effect of periodontal treatment on glucose levels in patients without diabetes has not been reported. Although patients with diagnosed diabetes were excluded from participating in this study, 15% of the participants had glucose levels above 6.0 mmol/L at baseline. This is consistent with a study by Borrell et al. [17], which showed that the risk of undiagnosed diabetes increases with the presence of periodontitis.

Although the levels of CRP did not decrease significantly, the mean decrease after 12 months (0.45 g/L) is comparable to data.

*a Normal distribution.
presented in a recent meta-analysis [18]. Whether CRP really is an independent risk factor for CVD remains debatable [19], however studies have shown that even small differences in CRP concentrations can reflect the risk of developing CVD [20]. In the present study, 12% of those examined at baseline did not come to the 3-month examination and 21% did not come to the 1-year follow-up. However, there were no significant differences in age, gender, smoking and levels of well-established risk factors such as CRP, glucose and cholesterol between those that dropped out and those who completed the study.

Treatment significantly and substantially decreased plasma concentrations of IL-18 and IFN-γ. The decrease of IL-18 could be of interest, since plasma concentrations of this cytokine are elevated in individuals with CVD [21]. This is especially so given that the decrease in IL-18 levels also correlates with better periodontal health. Plasma IL-18 has also been shown to predict death in patients with a pre-existing CVD [22] and also death in initially healthy individuals [23]. Animal models support the role of IL-18 in atherogenesis, and this role has been shown to partly involve an IFN-γ-dependent mechanism [24]. However, one must remember that no reductions were observed for the majority of the inflammatory markers that were investigated.

IFN-γ plays a role in the development of atherosclerosis, both as a consequence of its effects on plaque progression/stability [25,26] and via its negative impact on blood lipid trafficking (for review see Leon and Zuckerman [27]). In our present study, treatment reduced the plasma concentration of IFN-γ by more than 90%. The influence of treatment on IL-18 and IFN-γ levels appeared to be specific, as it had no effect on the levels of IL-1β, IL-4, IL-5, IL-6, IL-8, IL-10 and TNF-α. This is somewhat surprising since the levels of some of these cytokines at baseline, most notably IL-4 and IL-8, are different to those that are present in a matched control group of periodontally healthy subjects [28].

Although there were differences in the concentrations of antibodies against heat shock proteins between the patients in this study and a matched control group [28], treatment had no effect on these.

In the present study, all patients had severe chronic periodontitis with, on average, 48 periodontal pockets. In combination with a ‘high bleeding on probing’ index (45%), this signifies there to have been a severe and widespread periodontal inflammation and thus it is likely that there was a potentially deleterious total body inflammatory load. The local clinical signs of this periodontal inflammatory burden were significantly reduced following periodontal treatment and the total body load of inflammation was thus considerably decreased. This, in turn, is likely to have an impact on other (systemic) diseases with an inflammatory origin. In conclusion, standard treatment of severe periodontal disease induces systemic changes in several biochemical markers that reflect the risk for atherosclerosis. These findings are of significant relevance to our understanding of the association between these common diseases.
